Abstract—We propose a compact integration system to simultaneously provide wireline and wireless (baseband and ultra-wide band (UWB)) services to end-users in a WDM-PON. A 1-Gbps UWB signal is optically generated and shares the same wavelength with the baseband signal. Error-free performance was achieved after 23-km single mode fiber (SMF) transmission for both signals and additional 0.4-m wireless transmission for the UWB signal. The low complexity and high spectrum efficiency of this system makes it attractive for deployment of in wireline/wireless converged gigabit optical access networks.

Index Terms— Microwave photonics, passive optical network (PON), radio over fiber (RoF), ultra-wideband (UWB), wavelength division multiplexing (WDM).

I. INTRODUCTION

RECENTLY, there is a increasing demand from service providers to simultaneously support multiple wireline/wireless broadband services to end-users in a converged optical access network. A wavelength division multiplexed-passive optical network (WDM-PON) is considered as the backbone of a converged network for provision of both wireline and wireless services because it offers several advantages such as large bandwidth, long reach, high power budget, excellent security and easy upgradeability [1, 2].

Ultra-wide band (UWB) is a promising technology for short range wireless communication systems due to its low complexity, low cost, low power consumption and coexistence with other radio communication systems. Regulated by the Federal Communications Commission (FCC), UWB operating within the spectrum band 3.1-10.6 GHz has extremely low emission power at -41.3dBm/MHz [3]. As a result, achievable wireless transmission distance is limited in a few meters. To extend the reach of UWB services, UWB-over-fiber technologies with different schemes have been proposed recently [4-8]. Additionally, some works have demonstrated the possibility to increase the spectrum efficiency of WDM-PON networks and optical in-home networks by simultaneously transmitting baseband and the electrically generated UWB signals [9, 10]. The baseband signal is combined with the UWB signal using electrical combiner and then modulates an optical source. To further exploit the

advantages of photonic technologies such as high-speed generation and no requirement of combining electrical signals, it is desirable to directly generate and integrate the UWB signal in the optical domain.

In this letter, we propose and experimentally demonstrate a WDM-PON system that simultaneously provides gigabit baseband service and gigabit impulse UWB (IR-UWB) service on a single wavelength. The UWB signal is optically generated based on relaxation oscillations of a directly modulated laser (DML). Both signals were transmitted over 23 km of single mode fiber (SMF). The detected UWB signal was further transmitted over 0.4-m wireless link. Offline digital signal processing (DSP) receivers were employed to demodulate the signals and assess their bit-error-rate (BER) performance.

II. NETWORK ARCHITECTURE AND EXPERIMENTAL SYSTEM

Fig. 1 depicts the downlink topology of a WDM access network supporting wireline and UWB wireless services. A central office (CO) is composed of a laser array with n transmitters (TXs) which offer WDM wavelengths for downlink. Two arrayed waveguide gratings (AWGs) operate as a wavelength multiplexer and a demultiplexer, respectively. At the optical network unit (ONU) side, after a single mode fiber (SMF) link, a downstream receiver is used to demodulate the baseband signal, and a transmitting antenna is employed to radiate the UWB signal to the air. In this scenario, a number of ONUs in a cluster can share a single wavelength and broadcast services on this wavelength.

Fig. 2 shows the experimental system supporting optically generated IR-UWB and wireline baseband services. At the CO, for a channel, a high-speed baseband signal drove a directly modulated laser (DML) to generate a UWB signal based on relaxation oscillations [5]. The lightwave from the laser was launched into a Mach-Zender modulator (MZM) which was driven by the second baseband signal. Two optical tunable filters (OTFs) were used to emulate AWGs. The optical carrier was located at the right side slope of the OTF1 to modify the pulse shape of the UWB signal to better comply with the FCC mask [4]. The low frequency RF components can be greatly suppressed for the integration of baseband signals. The OTF2 simply suppressed amplified spontaneous emission (ASE) noise from erbium-doped fiber amplifier (EDFA). At the ONU, both the UWB and baseband data were recovered by a single photodetector (PD) and separated by proper filters. The UWB signal was then radiated into the air through a transmitting antenna.

Both the baseband and UWB data were demodulated offline employing a DSP receiver composed of a 40-GSa/s digital storage oscilloscope (DSO) and offline DSP algorithms. For the baseband data, the unfiltered detected signal from the PD was recorded. For the UWB data, the signal from the receiving antenna was amplified, filtered and then stored by the DSO.

III. EXPERIMENTAL RESULTS

In the experiment, lasing threshold current and bias current of the DML -21 mA and -34 mA, respectively. The DML was driven by a pulse pattern generator (PPG) at 12-Gbps and 0.625-V peak-to-peak voltage (V_{p-p}) with a pattern “1010 0000

0000” to present UWB bit “1” and a pattern “0000 0000 0000” to present UWB bit “0”. The effective bit rate for the generated UWB signal was thus 1 Gbps. The output optical carrier is then externally modulated by a 1-Gbps baseband PRBS with a word length of $2^{15}-1$ from the second PPG at the MZM. 3-dB bandwidth of two OTFs was 0.308 nm and 0.948 nm, respectively. The offset between the transmission wavelength and the central wavelength of OTF1 was 0.3 nm. The optical spectrum of the DML output and the bandwidth profiles of two OTFs are shown in Fig. 3. The bandwidth of the PD was 12-GHz. The UWB signal was radiated into the free space by an Omni-directional antenna (Skycross SMT-3TO10M-A). The wireless transmission distance was set at 0.4 m for demonstration purpose. The radiated UWB signal was received by a directive antenna (Geozondas AU-3.1G10.6G-1) pointed towards the transmitting antenna.

No electrical amplifier was used after the PD. In this condition, to ensure UWB spectrum was FCC-compliant, the maximum optical power launched to the PD was -12.5-dBm. Fig. 4 shows the electrical spectra after fiber transmission at this power. The effective mask is the allowed mask when the frequency response of the transmitting antenna was taken into account [8]. The baseband signal did not alter the spectrum of the UWB signal in the main frequency region (3-9 GHz). The detected hybrid waveform is shown in Fig. 5. There were two levels for the pulse amplitude of UWB bits “1” when they co-existed with baseband bits. Baseband bits “1” increased the pulse amplitude of UWB bits “1” when they overlapped in time domain. It is because the baseband signal modulated the intensity of the optical carrier after the UWB signal.

A. Performance of the UWB data

The DSP demodulation algorithm for the UWB signal comprised four steps: high-pass filtering, bit correlation, bit synchronization and threshold gating [6]. Fig. 6 illustrates the transmission performance of 50,000 generated UWB bits after 0.4-m wireless transmission, with and without the co-propagation of 0.5-V baseband data. There were no errors detected in all cases when the optical power was higher than -14 dBm. We can notice that 23-km fiber transmission introduced about 2-dB power penalty which is mainly caused by fiber chromatic dispersion. It was because relaxation oscillations of direct modulation broadened the spectrum of the optical signal from the DML and the UWB signal occupied a broad bandwidth. Moreover, the co-propagation of baseband signal caused approximately 1-dB power penalty.

As two signals share the same optical carrier, there is a trade-off between their performances [2]. To further assess the effect of the baseband signal on the performance of the UWB signal, we varied the V_{p-p} of the baseband data while the optical power at the receiver was fixed at -12.5 dBm. No error was detected in 50,000 bits when the V_{p-p} was below 0.625 V as presented in Fig. 7. When the V_{p-p} increased from 0.75 V to 1.0 V, BER of the UWB signal increased from 1.26×10^{-4} to 2.51×10^{-3} . At this optical power level, for the baseband data, $\text{BER} < 10^{-9}$ could be achieved at 0.250-V V_{p-p} as presented in next section. The inset shows the eye-diagram after DSP processing for the case with the baseband data.

Fig. 7. BER of the UWB signal at different V_{p-p} of the baseband signal. Inset: measured eye-diagram with 0.5-V baseband signal.

Fig. 8. Measured BER of the baseband signal. Inset: the eye-diagram at -18dBm after 23-km transmission.

B. Performance of the baseband data

The DSP algorithms for baseband signal included low-pass filtering with 900-MHz cut-off frequency, synchronization and threshold decision. This cut-off frequency ensures that the repetition frequency at 1GHz of the UWB signal is rejected to reduce the interference from the UWB signal. Fig. 8 shows the measured BER curves of 100,000-bit baseband data at different V_{p-p} . We can notice that at the same optical power to the PD, BER decreased with the increase of V_{p-p} . In a linear transmission system, $\log(-\log(\text{BER}))$ is proportional to the received optical power, therefore by extrapolating the BER curve, error-free transmission ($\text{BER} < 10^{-9}$) is predicted to be able to achieve at -21 dBm to -15 dBm when the V_{p-p} was decreased from 1.0 V to 0.25 V. The power penalty induced by after 23-km fiber transmission is negligible as it can be seen from the 0.5-V modulation case. The inset shows the measured eye-diagram after transmission at -18-dBm optical power. At this optical power, $\text{BER} < 10^{-9}$ could be achieved.

The experimental results show the existence of the trade-off between the performance of the baseband and UWB signals. The higher modulation index of the baseband signal, the better the performance of baseband data but the worse the performance of the UWB data. We also can notice that the required optical power for the baseband data to reach the forward error correction (FEC) limit ($\text{BER} < 2 \times 10^{-3}$) was always

lower than that for the UWB service even at the driving voltage of 0.25-V. To satisfy performance requirement for both the data at a fixed optical power level, the V_{p-p} of the baseband signal can be further reduced. With such low modulation depth, the optical carrier can be reused for uplink baseband data transmission in reflective semiconductor optical amplifier (RSOA) based WDM-PON systems [1, 2]. On the other hand, to improve the performance of the UWB signal at low optical power, an electrical amplifier with a power control mechanism can be used for the UWB signal. In this condition, the optical power budget for splitting and transmission is increased.

IV. CONCLUSIONS

A novel scheme for simultaneous provision of optically generated gigabit UWB and baseband services on a single wavelength of a WDM-PON system was proposed and experimentally demonstrated. No error was observed for 1-Gbps baseband data and 1Gbps IR-UWB data after 23-km fiber transmission. The existence of the baseband data caused about 1-dB power penalty on the performance of the UWB data. The integration of the UWB signals into the baseband WDM-PON increases electrical/ optical spectrum efficiency of the whole systems, and thus it has great potential for applications in supporting the development of wireline/wireless convergence in optical access networks.
